(Dated: December 7, 2009)

It is shown that the jump in the momentum distribution of Fermi gases evolves smoothly for small and intermediate times once an interaction between the fermions is suddenly switched on. The jump does not vanish abruptly. The loci in momentum space where the jumps occur are those of the noninteracting Fermi sea. No relaxation of the Fermi surface geometry takes place.

PACS numbers: 05.70.Ln, 71.10.Fd, 05.30.Fk

Recently, the interest in nonequilibrium quantum physics has risen significantly. This is due to experimental and theoretical progress in treating quantum systems with time dependent parameters. No exhaustive overview of the field is possible but we mention the manipulation of atoms in optical lattices [1] and time-dependent transitions between distinct many-body states in particular [2] on the experimental side. Sudden changes due to heating by ultrashort laser pulses make time-dependent investigations also possible in solid state systems [3]. On the theoretical side, there have been important advancements in new techniques, e.g., time-dependent density-matrix renormalization [4, 5] and numerical renormalization [6], nonequilibrium dynamical mean-field theory (DMFT) [7, 8, 9] or forward-backward continuous unitary transformations (CUTs) [10].

The main issues investigated presently are (i) the description of nonequilibrium stationary states and (ii) how various quenched physical systems approach such states or equilibrium states. The existence of conserved quantities can imply that equilibrium Gibbs states are not reached. The systems may approach generalized Gibbs states [11] which include the knowledge of the conserved quantities, see e.g. Ref. 8. In particular, integrable systems with their macroscopic number of conserved quantities play a special role which may lead to more subtle stationary behavior [12]. The precise way how the stationary states are approached is investigated intensively by analytical [13, 14, 15] and numerical means [16, 17, 18].

In the present article, we do not focus on thermalization itself but on the regime before, i.e., for short and intermediate times after the quench. We consider interaction quenches of Fermi gases at zero temperature. We study how the ground state $|0\rangle$ (Fermi sea) of a noninteracting fermionic systems evolves once an interaction is suddenly switched on. This question has been investigated in the continuum field theory of a Tomonaga-Luttinger (TL) model [14, 19] in one dimension (1D). In leading second order in the interaction U of the Hubbard model in $d > 1$ dimension, the behavior of the momentum distribution (MD) was elucidated by CUTs [10].

Very recently, nonequilibrium DMFT was used to study the issue for $d = \infty$ dimensions [9].

The latter studies motivate our investigation in particular. The numerical data [9] has been consistently analyzed in terms of a finite jump $\Delta n(t) := \lim_{k \rightarrow k_F} n_t(k) - \lim_{k \rightarrow k_F} n_t(k) > 0$ in the MD

$$n_t(k) = \langle 0 | e^{itH} c_k^\dagger c_k e^{-itH} | 0 \rangle \quad (1)$$

which decreases quickly. If the interaction is large enough oscillatory behavior in $\Delta n(t)$ is found. This was also seen in the numerical analysis of spinless 1D fermions [17].

In their study of prethermalization Moeckel and Kehrein also discuss the short and intermediate time behavior and state that the fermions at the Fermi momentum acquire a finite life due to fourth order processes [10]. Thus they presume that the jump collapses immediately after the quench. The width Δk , over which the jump is broadened, is small of the order of $(\rho_F U)^4$ where ρ_F is the density-of-states at the Fermi level.

In view of these contradictory results we aim at elucidating the behavior of the MD at small and intermediate times. We provide evidence that the MD displays a jump without broadening. The quintessential reason is that long-range correlations of the quenched system remain determined by the system before the quench.

First, we revisit the 1D TL model and extend Cazalilla's results [14, 19] to small and intermediate times. A finite jump occurs computed for all times in all orders of the interaction [25]. Recall that the scattering processes are particularly strong in 1D: They destroy the conventional Fermi liquid. Thus the survival of a finite MD jump in $d = 1$ can be seen as evidence for the persistence of the MD jump also in higher dimensions although an alternative view is to take the 1D situation as being too special to deduce generic behavior in higher dimensions. Hence, in order to support our view that the 1D behavior is generic for the *short and intermediate times* after a quench we secondly discuss the general situation in the Heisenberg picture.

a. Tomonaga-Luttinger Model 1D fermionic models with linear dispersion and without Umklapp scattering can be mapped to free bosonic models, see e.g. Refs. 20, 21, 22. For simplicity, we first consider spinless fermions

with the bosonized Hamiltonian in momentum space

$$H = \sum_{q \neq 0} \tilde{v} |q| b_q^\dagger b_q + \frac{1}{2\pi} \sum_{q \neq 0} U(q) |q| (b_{-q}^\dagger b_q^\dagger + b_{-q} b_q) \quad (2)$$

where $\tilde{v}$ is the bare Fermi velocity and $U(q)$ is essentially the Fourier transform of the density-density interaction [23]. The noninteracting Hamiltonian H_0 is the one with $U(q) = 0$. Contributions at $q = 0$ are left out because they do not matter in the sequel. The bosonic creation operator is given in terms of the fermionic creation (annihilation) operators $c_k^\dagger$ (c_k) by $b_q^\dagger = i\sqrt{2\pi/(|q|L)} \sum_k c_{k+q}^\dagger c_k$ where L is the length of the periodic system. For the MD around the right Fermi point at k_F we need the 1-particle correlation

$$G_R(x, t) = -i \langle 0 | \hat{\psi}_R(x, t) \hat{\psi}_R(0, t) | 0 \rangle \quad (3)$$

where $\hat{\psi}_R(x, t) = e^{itH} \hat{\psi}_R(x) e^{-itH}$ is the annihilating real-space field operator of the right-movers (subscript L is for left-movers) at site x [20, 23]. Fourier transform of $G_R(x, t)$ to momentum space provides the wanted MD. The standard bosonization identity [20, 21, 22, 23] reads

$$\hat{\psi}_R(x) = e^{-i\varphi_R^\dagger(x)} e^{-i\varphi_R(x)} U_R^- e^{(2\pi i x/L)(\hat{N}_R - \frac{1}{2})} / \sqrt{L}, \quad (4)$$

where U_R^- is the Klein factor decreasing the number $\hat{N}_R$ of right-movers by one. The bosonic field φ is given by $\varphi_\alpha(x) = -\sigma_\alpha \sum_{\sigma_\alpha q > 0} \sqrt{2\pi/(|q|L)} b_q e^{iqx - a|q|/2}$ where $\alpha \in \{R, L\}$ and $\sigma_R = 1$ ($\sigma_L = -1$). Finally, the convergence factor a will be sent to $0+$.

For evaluating $G_R(x, t)$ we need the time-dependent operator $\hat{\psi}_R(x, t)$ which is given by (4) with $\varphi_R(x)$ being replaced by $\varphi_\alpha(x, t) = e^{itH} \varphi_\alpha(x) e^{-itH}$. This operator can be computed if H in (2) is diagonalized by the appropriate Bogoliubov transform $b_q = C \tilde{b}_q + S \tilde{b}_{-q}^\dagger$ with $C = \cosh \theta_q$ and $S = \sinh \theta_q$. The diagonalized Hamiltonian $H = E_0 + \sum_{q \neq 0} v |q| \tilde{b}_q^\dagger \tilde{b}_q$ is characterized by the velocity v . For q -independent θ_q the calculation is particularly transparent. Applying the Bogoliubov transform forward and backward [10, 14] we eventually obtain

$$\begin{aligned} \varphi_R(x, t) = & C^2 \varphi_R(x - vt) + SC \varphi_L^\dagger(x - vt) \\ & - SC \varphi_L^\dagger(x + vt) - S^2 \varphi_R(x + vt). \end{aligned} \quad (5)$$

Combining this result with the time-dependent version of (4) and inserting it in (3) yields the expectation value of the product of exponentials in $\varphi_\alpha^{(\dagger)}(x \pm vt)$ and $\varphi_\alpha^{(\dagger)}(\pm vt)$. Such a product can be evaluated by bringing the annihilating operators φ to the right and the creating operators $\varphi^\dagger$ to the left with the help of the Baker-Campbell-Hausdorff formula $e^A e^B = e^{A+B+[A,B]/2}$ if $[A, B]$ is a number only. The required commutators are $[\varphi_\alpha(x), \varphi_\alpha^\dagger(x')] = -\ln(2\pi i(\sigma_\alpha(x' - x) - ia)/L)$. The final result reads

$$G_R(x, t) = \frac{e^{ik_F x}}{2\pi(x + ia)} f(v, r)^{2\gamma(1+\gamma)} \quad (6)$$

$$f(v, r) = \frac{r^2}{r^2 + (2vt)^2} \frac{|(x + ir)^2 - (2vt)^2|}{r^2 + x^2}, \quad (7)$$

with $\gamma := S^2 = \mathcal{O}(U(0)^2)$. For q independent interaction one has r in (7) is given by the convergence factor a which spoils the proper limit $a \rightarrow 0+$. Conventionally, this is solved by taking into account that the interaction is not completely local but has a range r . In equilibrium calculations the most convenient assumption is $\sinh^2 \theta_q = \gamma e^{-r|q|}$ [20, 24]. In the present nonequilibrium context it is more convenient to assume $\sinh^2 \theta_q (1 + \sinh^2 \theta_q) = \gamma(1 + \gamma) e^{-r|q|}$ which allows us to discuss Eq. (6) rigorously at $a = 0+$ for all times t and distances x . In this case, the above sketched derivation must be done for each pair of modes $q, -q$ and the commutators finally imply (6,7). For comparison, we remind the reader that the equilibrium correlation [20] reads $G_{R,eq}(x) = \frac{e^{ik_F x}}{2\pi(x + ia)} \left(\frac{r^2}{r^2 + x^2} \right)^\gamma$.

FIG. 1: (color online) Time evolution of the momentum distribution $n_t(k)$ around the right Fermi point $k_F > 0$ ($\Delta k := k - k_F$) for the spinless TL-model with $\gamma = 0.1$.

For $t = 0$ in (6,7), $f(v, r) = 1$ holds and the MD resulting from the Fourier transform of $e^{ik_F x}/(2\pi(x + i0+))$ is the expected step function of the Fermi sea, cf. Fig. 1. For $t = \infty$ we have $f(v, r) = r^2/(r^2 + x^2)$ which implies a power law $n(k) - 1/2 \propto \Delta k^{4\gamma(1+\gamma)}$ without a jump. Although a stationary correlation has been reached no thermalization has taken place because of the simplicity of the model: macroscopic number of conserved quantities, too little variation in the dispersion [14, 15].

We focus on small and intermediate times for which we find that $G_R(x, t)$ decreases always like $1/x$ which implies a finite jump at the Fermi vector. The time-dependent prefactor of $1/x$ is given by the first fraction $r^2/(r^2 + (2vt)^2)$ in (7) to the power $2\gamma(1+\gamma)$ which agrees for $t \rightarrow \infty$ with previous analyses [14, 19]. Hence there is a completely smooth decrease of the jump

$$\Delta n(t) = [r^2/(r^2 + (2vt)^2)]^{2\gamma(1+\gamma)}, \quad (8)$$

remaining finite at all finite times. The complete MD at various times is obtained by numerical Fourier transformation; see Fig. 1. In the estimate $r/v \approx \hbar/J = \mathcal{O}(1\text{ms})$

J is the hopping element from site to site which leads to the stated time scales for atoms in optical lattices [1, 2]. The MD $n_t(k)$ at given k does not evolve monotonically in time but displays oscillations in line with previous perturbative [10] and numerical [17] results.

Inspecting (5) it is obvious why the $1/x$ proportionality of $G_R(x, t)$ does not change in the course of time. The operator $\varphi_R(x, t)$ propagates through space at maximum with speed v . Hence there is no way how for a given time the long distance behavior is changed. This argument relies on the existence of a maximum speed $v_{\max} < \infty$ by which information can travel through the system. This phenomenon was called light-cone effect by Calabrese and Cardy [13]; they used the term for the propagation of entangled quasiparticles a quench. Note for later discussion that such a maximum speed generally exists independently of the system's dimension.

But the prefactor of the $1/x$ correlation changes in time in spite of the light-cone effect. This represents a major change in the correlations. Inspecting our derivation we see that this effect stems from local commutators, i.e., from commutators between $\varphi_\alpha(x \pm vt)$ and $\varphi_\alpha^\dagger(x \mp vt)$ or from the corresponding pair at $x = 0$. Thus there is a multiplicative renormalization of the matrix element which links $\hat{\psi}^\dagger(x, t)_R|0\rangle$ to $\hat{\psi}^\dagger(x)_R|0\rangle$. Below we show that this is also the generic situation in higher dimensions. Here we point out that for the behavior over short distances and short times the TL model is not special. All corrections which might be induced by other terms, which are present in more general models, will not change the qualitative behavior found here because they can be treated for short distances and times perturbatively.

For completeness we wish to extend the results for the spinless TL model to its counterpart with spin where charge (c) and spin (s) bosonic operators arise from the symmetric and antisymmetric, respectively, combination of the $\uparrow$ and $\downarrow$ bosonic operators [20, 21]. The Hamiltonian is diagonal in charge and spin bosons. It is characterized by the charge triple v_c, r_c, γ_c and the spin triple v_s, r_s, γ_s . In the extended boson identity (4) the sum of the charge $\varphi_{R,c}$ and the spin $\varphi_{R,s}$ modes occur multiplied by $1/\sqrt{2}$ due to normalization [20]. Pursuing the same manipulations as in the spinless case eventually leads to

$$G_R(x, t) = \frac{e^{ik_F x}}{2\pi(x + ia)} f(v_c, r_c)^{\gamma_c(1+\gamma_c)} f(v_s, r_s)^{\gamma_s(1+\gamma_s)}. \quad (9)$$

On the one hand, many qualitative features are the same as in the spinless case, in particular the persistence of a finite jump in the MD for all times. It is given by

$$\Delta n(t) = \left[\frac{r_c^2}{r_c^2 + (2v_c t)^2} \right]^{\gamma_c(1+\gamma_c)} \left[\frac{r_s^2}{r_s^2 + (2v_s t)^2} \right]^{\gamma_s(1+\gamma_s)}. \quad (10)$$

On the other hand, the appearance of two velocities, two length scales and two exponents which are possibly different leads to a richer phenomenology. We refrain from showing explicit results because the MDs look very similar to the ones in Fig. 1. The difference in the decrease

with the distance x between Eqs. (6) and (9) is hardly discernible. Hence spin-charge separation, i.e., the difference $v_c \neq v_s$ is visible only in high precision measurements.

b. General Interacting Fermions Because the scattering induced by interaction is particularly strong in 1D, the persistence of the MD jump in 1D indicates that it should persist in higher dimensions as well. Alternatively, one may presume the persistence of the jump to be peculiar to 1D. To support our view that the persistence is generic we will analyze the general equations of motion below. Note that in all dimensions a maximum speed $v_{\max} < \infty$ exists at which operators can propagate. Thus the long range behavior of correlations cannot change within a finite times.

To be specific we consider the 1-particle correlation $G(\mathbf{r}, t) = -i\langle 0|\hat{\psi}(\mathbf{r}, t)\hat{\psi}^\dagger(\mathbf{0}, t)|0\rangle$ where the Heisenberg time evolution of the operators is induced by the interacting Hamiltonian H while $|0\rangle$ is the Fermi sea of the noninteracting Hamiltonian H_0 . A spin dependence is omitted for simplicity. The Heisenberg equation reads $\partial_t \hat{\psi}^\dagger(\mathbf{r}, t) = i[H, \hat{\psi}^\dagger(\mathbf{r}, t)]$. The commutation with H_0 (Liouville operator L_0) will propagate the 1-particle operator only. The commutation with the interaction (L_I) generates a particle-hole (PH) pair. The iteration of L_I increases the number of particle-hole pairs. Hence the structure of the solution is

$$\hat{\psi}^\dagger(\mathbf{r}, t) = P_{\mathbf{r}}^\dagger + P^\dagger(P^\dagger H^\dagger)_{\mathbf{r}} + P^\dagger(P^\dagger H^\dagger)_{\mathbf{r}}^2 + \dots \quad (11)$$

where $P^\dagger$ ($H^\dagger$) stands for a created particle (hole). It is understood that each term in (11) is normal-ordered relative to the Fermi sea $|0\rangle$. The application L_0 will reproduce the structure of a term $P^\dagger(P^\dagger H^\dagger)_{\mathbf{r}}^m$, i.e., m stays fixed, while L_I can increase m by one, leave it unchanged, decrease it by one or by two. The first two terms in (11) are denoted explicitly in d dimensions

$$P_{\mathbf{r}}^\dagger = \int_{|\mathbf{r}_1| < v_{\max} t} h_0(\mathbf{r}_1, t) : \hat{\psi}^\dagger(\mathbf{r}_1 + \mathbf{r}) : d^d r_1 \quad (12)$$

$$P^\dagger(P^\dagger H^\dagger)_{\mathbf{r}} = \iiint_{|\mathbf{r}_j| < v_{\max} t} h_1(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, t) : \hat{\psi}^\dagger(\mathbf{r}_1 + \mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}_2 + \mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}_3 + \mathbf{r}) : d^d r_1 d^d r_2 d^d r_3. \quad (13)$$

The Heisenberg equation generates a hierarchy of coupled differential equations for the $h_m(\{\mathbf{r}_j\}, t)$. Because $h_m(\{\mathbf{r}_j\}, 0) = 0$ for $m > 0$ and a term with m PH pairs requires at least m applications of L_I we know $h_m = \mathcal{O}(U t)^m$ where U is a generic value of the interaction. The expansion in t can be computed order by order. Though we cannot prove the convergence of the series t we do not see any means that the radius of convergence vanishes for Hamiltonians with finite coefficients. Certainly, the hierarchy is finite and thus well-behaved if calculations up to a finite order in the interaction, e.g., U^4 , are carried out.

For $G(\mathbf{r}, t)$ the expectation value $\langle 0|\hat{\psi}(\mathbf{r}, t)\hat{\psi}^\dagger(\mathbf{0}, t)|0\rangle$ must be evaluated which contains terms like

$$\langle 0|(HP)^m P_{\mathbf{r}} P^\dagger(P^\dagger H^\dagger)_{\mathbf{0}}^j \rangle = \delta_{m,j} G^{(2m+1)}(\mathbf{r}, t) \quad (14)$$

because only states with the same number of PH pairs can have a finite overlap. The Wick theorem is applicable because $|0\rangle$ is a Fermi sea so that the many-particle correlations can be reduced to products of the initial 1-particle correlations $g(\mathbf{r}) := G(\mathbf{r}, 0)$. Thus we know $G^{(2m+1)}(\mathbf{r}, t) = \mathcal{O}(g(\mathbf{r})^{2m+1})$. The information about the jump is encoded in the most slowly decreasing contribution for $|\mathbf{r}| \rightarrow \infty$, namely the one for $m = 0$

$$G^{(1)}(\mathbf{r}, t) = \iint_{|\mathbf{r}_j| < v_{\max} t} h_0^*(\mathbf{r}_1, t) \cdot g(\mathbf{r} + \mathbf{r}_1 - \mathbf{r}_2) h_0(\mathbf{r}_2, t) d^d r_1 d^d r_2. \quad (15)$$

This double convolution implies $n_t^{(1)}(\mathbf{k}) = n_0(\mathbf{k})|h_0(\mathbf{k}, t)|^2$ in momentum space where $n_0(\mathbf{k}) \in \{0, 1\}$ is the noninteracting MD. Clearly, the nonequilibrium 1-particle correlations inherit many of their qualitative properties from the 1-particle correlations before the quench. Interestingly, the jumps in the MD occur at the same loci where the noninteracting MD $n_0(\mathbf{k})$ jumps, i.e., at the noninteracting Fermi surface FS_0 . The reduction of the jump is given by

$$\Delta n(t)|_{\mathbf{k} \in \text{FS}_0} = |h_0(\mathbf{k}, t)|^2|_{\mathbf{k} \in \text{FS}_0}. \quad (16)$$

The Fourier transform $h_0(\mathbf{k}, t)$ corresponds exactly to $h_{k\uparrow}$ in Ref. 10 after the forward-backward CUT. These gen-

eral equations set the stage for the analysis of higher dimensional systems and allow us to draw general conclusions. Further analysis has to be numerical and it is therefore left to future research.

c. Conclusions Summarizing, we studied interaction quenches of noninteracting Fermi gases. The focus was the question how the jump in the momentum distribution (MD) vanishes. In 1D the Tomonaga-Luttinger model was investigated quantitatively and in higher dimension the general equations of motions were set up. For generic Hamiltonians without diverging coefficients we showed that the jump survives for small and intermediate times, displaying a smooth behavior as function of time. If thermalization takes place, we expect that the jump decreases exponentially (with or without oscillations).

We found that the quenched MD still displays many qualitative features of the noninteracting Fermi sea. In particular, the loci of the jumps are those of the Fermi sea. The Fermi surface of isolated quenched interacting fermion models does not evolve at all. The models have to be extended in order to incorporate relaxation of the Fermi surface geometry. Finally, we point out that the approach used here for the general situation can also be extended to correlations of two or more particles.

We gratefully acknowledge many helpful discussions with F.B. Anders and S. Kehrein.

 - [25] We assume that the interaction can be tuned so that zero interaction is accessible. If this is experimentally not possible no jump in the mathematical sense will occur in 1D because even a small interaction implies a continuous MD. But the deviation in the sense of a $\mathcal{L}_2$ norm from a real jump tends to zero for vanishing interaction so that for practical purposes, i.e., measurements with finite resolution, this fundamental aspect will not dominate.
